11 Running head: Amphistomy advantage in ‘ilima

12 ABSTRACT —

13 **Premise of the study** The adaptive significance of stomata on both upper and lower leaf surfaces, called
14 amphistomy, is unresolved. A widespread association between amphistomy and open, sunny habitats
15 suggests the adaptive benefit of amphistomy may be greatest in these contexts, but this hypothesis has
16 not been tested experimentally. Understanding why amphistomy evolves can inform its potential as a
17 target for crop improvement and paleoenvironment reconstruction.

18 **Methods** We developed a new method to quantify “amphistomy advantage”, AA, as the log-ratio of pho-
19 tosynthesis in an amphistomatous leaf to that of the same leaf but with gas exchange blocked through the
20 upper (adaxial) surface, which we term “pseudohypostomy”. We used humidity to modulate stomatal
21 conductance and thus compare photosynthetic rates at the same total stomatal conductance. We esti-
22 mated AA and related physiological and anatomical traits in 12 populations, six coastal (open, sunny)
23 and six montane (closed, shaded), of the indigenous Hawaiian species ‘ilima (*Sida fallax*).

24 **Key results** Coastal ‘ilima leaves benefit 4 times more from amphistomy compared to their montane
25 counterparts. Our evidence was equivocal with respect to two hypotheses – that coastal leaves bene-
26 fit more because 1) they are thicker and therefore have lower CO₂ conductance through the internal
27 airspace, and 2) that they benefit more because they have similar conductance on each surface, as op-
28 posed to most of the conductance being on the lower (abaxial) surface.

29 **Conclusions** This is the first direct experimental evidence that amphistomy *per se* increases photo-
30 synthesis, consistent with the hypothesis that parallel pathways through upper and lower mesophyll
31 increase the supply of CO₂ to chloroplasts. The prevalence of amphistomatous leaves in open, sunny
32 habitats can partially be explained the increased benefit of amphistomy in ‘sun’ leaves, but the mecha-
33 nistic basis of this observation is an area for future research.

34 **Keywords:** amphstomy, leaf, light, Hawai‘i, *Sida fallax*, stomata

35 INTRODUCTION —

36 Amphistomy, the presence of stomata on both lower and upper surfaces of broad leaves, should in-
37 crease carbon gain by reducing the average diffusion pathlength between stomata and chloroplasts, yet
38 paradoxically this seemingly simple adaptation is uncommon in nature and we don't know why. Un-
39 derstanding variation in stomatal traits like amphistomy is imperative because these tiny pores play
40 an outsized ecological role in the global carbon and water cycles (Hetherington and Woodward, 2003;
41 Berry et al., 2010). A widely applicable, accurate representation of how stomata mediate the relation-
42 ship between CO₂ gained through photosynthesis and water lost through transpiration is essential to
43 predict future climate using Earth Systems Models (Jarvis, 1976; Ball et al., 1987; Collatz et al., 1991;
44 Leuning, 1995; Sellers et al., 1997). Optimality models accurately predict the major cause of water loss,
45 stomatal conductance (g_{sw}), by assuming plants maximize carbon gain minus a cost of water (Cowan
46 and Farquhar, 1977; Givnish, 1986; Medlyn et al., 2011; Lin et al., 2015; Wang et al., 2017; Franks et
47 al., 2018; Deans et al., 2020; Franklin et al., 2020; Wang et al., 2020; Harrison et al., 2021). Despite
48 the success of optimality modeling in predicting g_{sw} , the same modeling approach has so far failed to
49 explain the rarity of amphistomatous leaves (Muir, 2019). **This gap between theory and observa-**
50 **tions strongly implies that we remain ignorant about some key benefits and costs associated with**
51 **stomata.**

52 Where are amphistomatous leaves found and why aren't they more common? Among terrestrial flower-
53 ing plants, amphistomatous leaves are rarely found on woody plants and shade-tolerant herbs, but they
54 are common in annual and perennial herbs from sunny habitats (Salisbury, 1928; Parkhurst, 1978; Mott
55 et al., 1982; Peat and Fitter, 1994; Gibson, 1996; Jordan et al., 2014; Muir, 2015, 2018; Bucher et al.,
56 2017). Even in resupinate leaves where the abaxial surface faces up toward the sky, stomata develop on
57 the lower adaxial surface (Lyshede, 2002). Exceptions to this general pattern include some arid woody
58 plants which typically have vertically oriented, isobilateral leaves (Wood, 1934; Jordan et al., 2014;
59 Boer et al., 2016; Drake et al., 2019) and floating/amphibious leaves of aquatic plants (Kaul, 1976;

60 Doll et al., 2021). The dearth of amphistomatous leaves should be quite surprising and has been de-
61 scribed as one of the most important unsolved problems in the study of leaf structure-function relations
62 despite some recent progress (Grubb, 1977, 2020).

63 Amphistomatous leaves should be common because, all else being equal, a leaf with a given number
64 of stomata per area could increase its photosynthetic rate simply by apportioning approximately half
65 its stomata to each surface (Parkhurst, 1978; Gutschick, 1984a, b). The key difference between a
66 hypo- and amphistomatous leaf, holding all other factors constant, is that an amphistomatous leaf has
67 two parallel diffusion paths through the internal airspace to any given chloroplast. Those airspaces
68 pose a resistance for CO₂ diffusion, so CO₂ concentration drops as it approaches chloroplasts. Shorter
69 pathways mean a smaller drop in CO₂ concentration. Thus, chloroplasts in amphistomatous leaves
70 experience higher CO₂ concentrations than in hypostomatous leaves, thereby increasing photosynthesis.
71 The airspace resistance (or its inverse, the airspace conductance, g_{ias}) is rarely measured directly and
72 there is disagreement between empirical (Parkhurst and Mott, 1990; Morison et al., 2005; Evans et al.,
73 2009; Tomás et al., 2013; Earles et al., 2018; Šantrůček et al., 2019; Nobel, 2020; Harwood et al., 2021;
74 Márquez et al., 2023) and theoretical models (Tholen and Zhu, 2011; Ho et al., 2016; Thérout-Rancourt
75 et al., 2021). The g_{ias} in thin, porous leaves may be so large as to be inconsequential given much lower
76 conductances for other components of the diffusion pathway, whereas the g_{ias} of thick leaves with
77 little airspace may greatly hinder CO₂ diffusion to chloroplasts. Amphistomy should confer the largest
78 photosynthetic benefit in leaves with intrinsically low g_{ias} . The airspace conductance is one component
79 of the overall mesophyll conductance, g_m , which is often strongly influenced by the chloroplast surface
80 area exposed to airspace and mesophyll cell wall thickness (Evans et al., 2009; Gago et al., 2020; Flexas
81 et al., 2021). Hence, thicker leaves may compensate for lower g_{ias} through increased chloroplast surface
82 area exposed to airspace (Terashima et al., 2006), but will still benefit from amphistomy as long as g_{ias}
83 is finite.

84 Amphistomy should also enhance photosynthesis when leaf boundary layer resistance is high, because

85 apportioning total flux between two boundary layers rather than one results in a smaller CO₂ concen-
86 tration drop between the atmosphere and stomata. A similar effect has been validated with a computer
87 model and measurements for transpiration: amphistomatous leaves lose somewhat more water for the
88 same vapor pressure deficit and total g_{sw} (Foster and Smith, 1986), but the additional carbon gain
89 should be enough to offset this cost under most realistic conditions (Muir, 2019). However, if mini-
90 mal stomatal conductance is related to stomatal density (Drake et al., 2013; Márquez et al., 2022) and
91 the upper boundary layer conductance is higher, then amphistomy could cause additional, unavoidable
92 water loss.

93 The most promising adaptive hypothesis is that amphistomy is important for maximizing photosynthetic
94 rate under high light. Mott et al. (1982) proposed that “plants with a high photosynthetic capacity,
95 living in full-sun environments, and experiencing rapidly fluctuating or continuously available soil
96 water” would benefit most, in terms of increased carbon gain, from having amphistomatous leaves.
97 As described above, herbs from sunny habitats are often amphistomatous. Most variation in stomatal
98 density ratio (SR, the ratio of stomatal density between the upper and lower surfaces) among species
99 is assumed to be genetic, but there is also putatively adaptive plasticity in response to light. Leaves of
100 *Ambrosia cordifolia*, a desert perennial herb, are hypostomatous under low light (photosynthetic photon
101 flux density, PPFD = 110 $\mu\text{mol m}^{-2} \text{s}^{-1}$) but develop ~20% of their stomata on the upper surface
102 under high light (1700 $\mu\text{mol m}^{-2} \text{s}^{-1}$) (Mott and Michaelson, 1991). Similarly, *Solanum lycopersicum*
103 leaves are hypostomatous when grown in the shade but develop ~20% of their stomata on the upper
104 surface grown under high light-intensity (Gay and Hurd, 1975). Adult leaves of *Eucalyptus globulus*
105 are amphistomatous, but the proportion of adaxial stomata increases from ~10-20% under low light
106 to ~30-40% under high light (James and Bell, 2001). In summary, both genetic and plastic responses
107 evince a widespread association between light and SR.

108 The association between high light and amphistomy suggests that ‘sun’ leaves have the most to gain in
109 terms of increased photosynthesis from having stomata on both surfaces, as Mott et al. (1982) hypoth-

esized. Parkhurst (1978) proposed quantifying this benefit as ‘amphistomy advantage’ (AA), which we adopt here with some modification (see Materials and Methods). This hypothesis has never been tested directly by comparing the photosynthetic rate of an amphistomatous leaf to that of an otherwise identical hypostomatous leaf with the same total stomatal conductance under the same conditions. We propose a straightforward method to do this by experimentally creating a pseudohypostomatous leaf with gas exchange blocked through the upper surface (see Materials and Methods). We use humidity to modulate stomatal conductance so that amphi- and pseudohypostomatous leaves can be compared at the same total stomatal conductance. One reason that sun leaves might have greater AA is that they are usually thicker or denser (Poorter et al., 2019), which will often result in lower g_{ias} either by increasing the diffusion path length (Parkhurst, 1978) or making the airspace less porous. A nonmutually exclusive hypothesis is that if sun leaves have a stomatal density ratio closer to 0.5 (same density on each leaf surface), this will confer a greater advantage than an amphistomatous leaf with most stomata on one surface. In other words, amphistomy doesn’t make much difference if one leaf surface has few open stomata on it. We therefore predict that sun leaves will have greater AA possibly because they have thicker leaves and/or SR closer to 0.5. We actually report $g_{smax, ratio}$, which is similar to SR except that it accounts for differences in both stomatal density and size between surfaces.

The native flora of the Hawaiian archipelago is an excellent system to test the relationship between light habitat and AA. Many lineages have adapted to different light habitats after colonization and leaf anatomical traits such as SR and thickness vary within and among closely related species. It is hypothesized that the common ancestor in many Hawaiian clades was a weedy species with high dispersal ability adapted to open habitats (Carlquist, 1966). Colonization was followed by adaptive radiation into higher elevation, montane, closed, forested habitats. Consequently, adaptation to sun and shade is a common axis of phenotypic variation among Hawaiian plants such as lobeliads (Givnish et al., 2004; Montgomery and Givnish, 2008; Givnish et al., 2009; Givnish and Montgomery, 2014; Scoffoni et al., 2015), *Bidens* (Carlquist, 1966; Knope et al., 2020), *Scaevola* (Robichaux and Pearcy, 1984; McKown et al., 2016), *Euphorbia* (Sporck, 2011), and *Plantago* (Dunbar-Co et al., 2009).

136 Here we focus on variation within an indigenous plant species *Sida fallax* Walp. (Malvaceae), known
137 in the Hawaiian language as ‘ilima. ‘Ilima is found from sea level to elevations > 1000 mas on mul-
138 tiple Hawaiian islands. Coastal populations are morphologically different from montane populations
139 (Fig. 1). Coastal regions of Hawai‘i are characterized by high sun exposure, warmer temperatures,
140 high winds, salinity, and variation in water availability. Coastal populations of ‘ilima tend to be short
141 and prostrate which likely helps them to withstand the windy environment (Fig. 1a). The leaves of
142 these populations are covered on both surfaces in dense, soft hairs that give the leaves a silvery green
143 appearance (Fig. 1b), which helps mitigate water loss by reflecting solar radiation, thereby lowering
144 leaf temperature (Ehleringer and Björkman, 1978). Montane regions, on the other hand, provide very
145 different challenges. Many other tall species grow on the slopes of these wet mountainous regions,
146 which makes light competition a factor that plants may need to adapt to. Possibly due to this, montane
147 populations are erect and shrub- or tree-like, capable of growing meters tall with strong, woody stems.
148 These individuals have smooth, green foliage with serrated edges. Montane populations exhibit traits
149 that may help them to compete for light availability. This montane morphology is not found in *S. fallax*
150 populations on other Pacific Islands (Pejhanmehr, 2022).

151 Because of their contrasting habitat and morphology, we treat leaves from coastal and montane plants as
152 representatives of sun and shade leaves, respectively, for testing hypotheses about amphistomy advan-
153 tage. Specifically, the objectives of our study are to test whether 1) sun leaves of coastal ‘ilima plants
154 will have greater AA than shade leaves of montane plants; and if so, is this because 2a) coastal plants
155 have thicker leaves than montane plants and/or 2b) coastal plants have a $g_{\text{smax, ratio}}$ closer to 0.5?

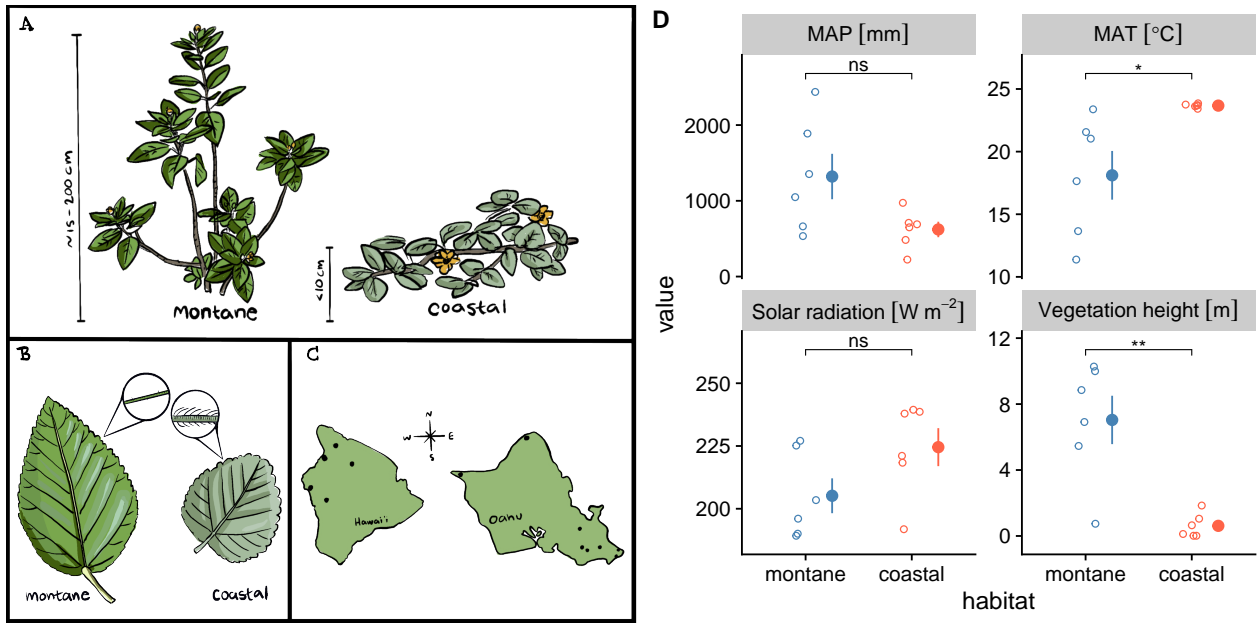

Figure 1: A. Typical growth form of montane (left) and coastal (right) 'ilima plants and B. leaves. C. Map of the sites that were sampled on the islands of O'ahu and Hawai'i (aka Big Island). D. Climatic, light, and vegetation height comparisons between montane (blue) and coastal (orange) habitats sampled in this study. Open circles are values for the midpoint of each site transect; closed circles and intervals are the mean \pm 1 standard error. The habitats differ significantly in mean annual precipitation (top-left), solar radiation (bottom-left), temperature (top-right), and vegetation height (bottom-right). MAP = mean annual precipitation; MAT = mean annual temperature; ns = not significant; * indicates $0.01 \leq P < 0.05$; ** indicates $0.001 \leq P < 0.01$.

MATERIALS AND METHODS —

Plant sampling and climate —

We identified 7 suitable natural populations of 'ilima on O'ahu and 5 on Hawai'i Island by consulting Yorkston and Daehler (2006) and citizen scientist records on iNaturalist (Anon, 2022) (Fig. 1c; Table 1). We avoided sites that appeared to be cultivated. We visited sites between August and November 2022. For logistical reasons, the sites on Hawai'i were sampled during one three-day trip. We haphazardly

sampled eight plants distributed evenly between the highest and lowest elevation plants along a transect at each site. For safety and conservation reasons, transects were along a trail or road. We did not sample small individuals if there was risk removing leaves would cause mortality. From each plant, we collected two fully expanded leaves for trait measurements. We sampled stomatal traits on all leaves; leaf thickness on one leaf from three randomly selected plants per site; and, due to limited time, a single leaf from a single plant at the middle of each transect for gas exchange measurements. We downloaded climatic data on mean annual temperature, solar radiation, and vegetation height from the Climate and Solar Radiation of Hawai'i databases (Giambelluca et al., 2014) using the latitude and longitude at the middle of each transect. We also downloaded mean annual precipitation from 1978-2007 from the Rainfall Atlas of Hawai'i (Giambelluca et al., 2013). The spatial resolution is approximately 234×250 m. The temperature data are calibrated from networks of meteorological stations operating in the late 20th century and 21st century; the solar radiation data are calibrated from satellite measurements collected between 2002 and 2009 (Giambelluca et al., 2014). We tested whether climatic variables differed among our coastal and montane populations using Welch's two-sample *t*-test.

Leaf traits —

Stomata —

We estimated the stomatal density and size on ab- and adaxial leaf surfaces from all leaves. For pubescent leaves (usually coastal), we dried and pressed leaves for ≈ 1 week (Hill et al., 2014), carefully scraped trichomes off with a razor blade, and rehydrated the leaf. Rehydration restores leaf area to its fresh value (Blonder et al., 2012). For glabrous leaves, we used fresh leaves. We applied clear nail polish to both leaf surfaces of fresh or rehydrated leaves in the middle of the lamina away from major veins. After nail polish dried, we mounted impressions on a microscope slide using transparent tape (Mott and Michaelson, 1991). We digitized a portion of each leaf surface impression using a brightfield

Table 1: 'Ilima study site location information.

Site	Island	Habitat	Latitude	Longitude	Elevation (mas)
Kahuku Point	O'ahu	coastal	21.710	-157.982	4
Kaloko beach	O'ahu	coastal	21.293	-157.661	4
Kaloko-Honokōhau national historical park	Hawai'i	coastal	19.676	-156.024	6

Mau'umae Ridge	O'ahu	montane	21.305	-157.779	248
Wa'ahila ridge	O'ahu	montane	21.314	-157.793	357

186 microscope (Leica DM2000, Wetzlar, Germany). We counted all stomata and divided by the visible
187 leaf area (0.890 mm^2) to estimate density and measured guard cell length from five randomly chosen
188 stomata per field using ImageJ (Schneider et al., 2012).

189 *Leaf thickness* —

190 We cut thin sections using two razor blades taped together. We sectioned the leaf in a petri dish of
191 water, wet-mounted sections onto a slide, and took digital micrographs using a brightfield microscope,
192 as described above. Leaf thickness is measured as the length from upper cuticle to lower cuticle.

194 At each site, we selected one representative leaf from one plant near the middle of the transect for
 195 gas exchange measurements using a portable infrared gas analyzer (LI-6800PF, LI-COR Biosciences,
 196 Lincoln, NE, USA). We estimated the photosynthetic rate (A) and stomatal conductance to water vapor
 197 (g_{sw}) at saturating light (photosynthetic photon flux density (PPFD) = $2000 \mu\text{mol m}^{-2} \text{s}^{-1}$), ambient
 198 CO_2 (415 ppm), and $T_{\text{leaf}} = 25.0\text{--}29.3^\circ\text{C}$. The midday irradiance in coastal 'ilima typically meets or
 199 even exceeds a PPFD of $2000 \mu\text{mol m}^{-2} \text{s}^{-1}$ and previous experiments with sun leaves revealed that
 200 $2000 \mu\text{mol m}^{-2} \text{s}^{-1}$ is always at or near saturating irradiance. Even though lower irradiance may be
 201 saturating for montane leaves, we used this higher value for all leaves to standardize conditions.

202 We also estimated ‘amphistomy advantage’ (AA) *sensu* Parkhurst (1978), but with modification. For
 203 each leaf, we measured the photosynthetic rate of an untreated amphistomatous leaf (A_{amphi}) over a
 204 range of g_{sw} values. We refer to this as an A – g_{sw} curve, which is described in more detail below. We
 205 compared the A – g_{sw} curve of the untreated leaf to the photosynthetic rate of pseudohypostomatous leaf
 206 (A_{hypo}), which is the same leaf but with gas exchange through the upper surface blocked by a neutral den-
 207 sity plastic (propafilm). Hypostomy refers to leaves with stomata only present on the lower, typically
 208 abaxial, surface. We refer to the untreated and partially blocked leaves as “amphi” and “pseudohypo”,
 209 respectively. AA is calculated as the log-response ratio of A compared at the same total g_{sw} :

$$\text{AA} = \log(A_{\text{amphi}}/A_{\text{hypo}})$$

210 The log-response ratio is commonly used social and biological sciences (e.g. Hedges et al. (1999)). It is
 211 straightforward to interpret because values above 0 indicate a photosynthetic advantage of amphistomy,
 212 whereas values less than 0 indicate a disadvantage. The log-response ratio is preferable to the absolute
 213 difference because it indicates a proportional change in A , which facilitates comparisons across leaves
 214 and environments with different baseline photosynthetic rates. The irradiance of the light source in

the pseudohypo leaf was higher because the propafilm reduces transmission. To compensate for reduced transmission, we increased incident PPFD for pseudohypo leaves by a factor $1/0.91$, the inverse of the measured transmissivity of the propafilm. We also set the stomatal conductance ratio, for purposes of calculating boundary layer conductance, to 0 for pseudohypo leaves following manufacturer directions.

Fig. S1 illustrates our method for collecting A - g_{sw} curves. We collected two curves per leaf, an amphi (untreated) curve and a pseudohypo (treated) curve. To control for order effects, we alternated between starting with amphi or pseudohypo leaf measurements. In the field, we acclimated the focal leaf to saturating light and high relative humidity ($RH = 70\%$), as described above, until A and g_{sw} reach their maximum. We used these data as our estimates of maximum A and g_{sw} . After that, we decreased RH to $\approx 10\%$ to induce rapid stomatal closure without biochemical downregulation. Hence, A_{amphi} and A_{hypo} were both measured at low chamber humidity after the leaf had acclimated to high humidity. All other environmental conditions in the leaf chamber remained the same. We logged data until g_{sw} reached its nadir. We then repeated the process of acclimating the leaf to 70% RH and inducing stomatal closure with low RH with the other treatment (amphi or pseudohypo). We did not detect an effect of treatment order on AA (results not shown).

Data analysis —

Objective 1: Do coastal leaves have greater amphi advantage than montane leaves? —

It is not feasible to record A_{amphi} and A_{hypo} at the exact same g_{sw} . To overcome this, we fit A - g_{sw} curves using a linear regression of $\log(g_{sw})$ on A to interpolate modeled A for amphi and pseudohypo leaves at the same g_{sw} . Let \hat{A}_{amphi} and \hat{A}_{hypo} be the estimated A of the amphi and pseudohypo leaves, respectively. We estimated these quantities at the same g_{sw} using fitted parameters ($\hat{\beta}$'s):

$$\hat{A}_{\text{amphi}} = \hat{\beta}_{0,\text{amphi}} + \hat{\beta}_{1,\text{amphi}} \times \log(g_{\text{sw}})$$

$$\hat{A}_{\text{hypo}} = \hat{\beta}_{0,\text{hypo}} + \hat{\beta}_{1,\text{hypo}} \times \log(g_{\text{sw}})$$

In 10 of 12 leaves, the minimum g_{sw} of the amphi curve was smaller than the maximum g_{sw} of the pseudohypo curve (i.e. the curves overlapped for a range of g_{sw} values). In those cases, we estimated \hat{A}_{amphi} and \hat{A}_{hypo} at the g_{sw} value in the middle of the range of overlap between the curves. In 2 of 12 leaves, the A - g_{sw} curves did not quite overlap because the minimum g_{sw} of the amphi curve was slightly greater than the maximum g_{sw} of the pseudohypo curve. In those cases, we estimated AA by extrapolating slightly, 1.98×10^{-3} and $3.29 \times 10^{-3} \text{ mol m}^{-2} \text{ s}^{-1}$, beyond the measured curves to the g_{sw} value in between the curves. The vertical lines in Fig. S2 show the g_{sw} for each leaf. AA for each leaf was calculated \hat{A}_{amphi} and \hat{A}_{hypo} using the log-response ratio shown above.

To estimate $\hat{\beta}$'s from the A - g_{sw} curve for each leaf, we fit Bayesian regressions using the *R* package **brms** version 2.20.1 (Bürkner, 2017) with MCMC sampling in *Stan* (Stan Development Team, 2023). We used CmdStan version 2.33.0 and **cmdstanr** version 0.6.1 (Gabry and Češnovar, 2023) to interface with *R* version 4.3.1 (R Core Team, 2023). We sampled the posterior distribution from 4 chains with 1000 iterations each after 1000 warmup iterations per chain. We estimated parameters and confidence intervals as the median and 95% quantile intervals of the posterior, respectively. The key prediction is that $\text{AA}_{\text{coastal}} > \text{AA}_{\text{montane}}$, meaning the 95% confidence intervals of $\text{AA}_{\text{coastal}} - \text{AA}_{\text{montane}}$ should be positive and not encompass 0.

Objective 2a: Are coastal leaves thicker than montane leaves? —

We tested whether leaf thickness (log-transformed) varied between coastal and montane populations and among individuals within populations using a Bayesian mixed-effects model with habitat as a fixed

effect and individual plant and site as random effects. We used the *R* package **brms** version 2.20.1 (Bürkner, 2017) to fit the model in *Stan* (Stan Development Team, 2023) with CmdStan version 2.33.0 and **cmdstanr** version 0.6.1 (Gabry and Češnovar, 2023). We sampled the posterior distribution from 4 chains with 1000 iterations each after 1000 warmup iterations per chain. We estimated the relationship between population average leaf thickness and AA measured from a single individual per population. We used this approach because most of the variation in leaf thickness was among sites and the plant selected for gas exchange measurements was not always among the plants randomly selected for leaf thickness, precluding individual level correlation. We propagated uncertainty about in AA and leaf thickness estimates by integrating over the entire posterior distribution sample for each variable. The key prediction is that the effect of leaf thickness on AA is positive, meaning the 95% confidence interval of the slope should be positive and not encompass 0.

Objective 2b: Is $g_{\text{smax, ratio}}$ closer to 0.5 in coastal leaves than montane leaves? —

We tested whether $g_{\text{smax, ratio}}$ varied between coastal and montane populations and among individuals within populations using a Bayesian multiresponse, mixed-effects model. The modeled response variables are stomatal count and guard cell length on each surface. Counts were modeled as negative binomially distributed variable from a latent stomatal density and a parameter ϕ to estimate overdispersion in counts relative to a Poisson model. For all traits, the explanatory variables were habitat as a fixed effect and leaf within individual plant, individual plant, and site as random effects. We used the *R* package **brms** version 2.20.1 (Bürkner, 2017) to fit the model in *Stan* (Stan Development Team, 2023) with CmdStan version 2.33.0 and **cmdstanr** version 0.6.1 (Gabry and Češnovar, 2023). We interpolated missing adaxial guard cell lengths from 6 out of 185 samples with zero adaxial stomata using the “mi” function in **brms** package. We sampled the posterior distribution from 4 chains with 1000 iterations each after 1000 warmup iterations per chain. From each posterior sample, we calculated $g_{\text{smax, ratio}}$ as:

$$g_{\text{smax, ratio}} = \frac{g_{\text{smax, upper}}}{g_{\text{smax, lower}} + g_{\text{smax, upper}}},$$

where $g_{\text{smax, lower}}$ and $g_{\text{smax, upper}}$ are maximum stomatal conductance to water vapor at $T_{\text{leaf}} = 25^\circ \text{C}$ on the lower and upper surface, respectively. The maximum stomatal conductance was calculated from stomatal density and length, assuming that stomata are fully open, following Sack and Buckley (2016):

$$g_{\text{smax}} = bmds^{0.5}.$$

In this equation, b is a biophysical constant, m is a morphological constant, d is the stomatal density, and s is the stomatal complex area. We assume that b , which is determined by the molecular species, temperature, and air pressure, is the same for both surfaces; we assume that m , which is determined by guard cell allometry is also the same for both surfaces. Hence, the b and m constants cancel out of $g_{\text{smax, ratio}}$ and only density and length (l), which is proportional to the square root of area, affect the ratio: $g_{\text{smax}} \propto dl$.

We estimated the relationship between leaf $g_{\text{smax, ratio}}$ and AA measured from a single leaf per population. We propagated uncertainty about AA and $g_{\text{smax, ratio}}$ by integrating over the entire posterior distribution sample for each variable. The key prediction is that the effect of $g_{\text{smax, ratio}}$ on AA is positive until $g_{\text{smax, ratio}} < 0.5$, meaning the 95% confidence interval of the slope should be positive and not encompass 0 in the domain $g_{\text{smax, ratio}} < 0.5$.

RESULTS —

Coastal 'ilima are surrounded by shorter vegetation than their montane counterparts (Fig. 1d; Welch Two Sample t -test, $t_{5.41} = 4.29$, $P = 0.007$). The montane site with the lowest vegetation height is a remnant dry forest (Koai'a tree sanctuary) in a matrix of cattle pasture, hence the satellite derived vegetation height may be lower than what existed prior to human disturbance. Coastal sites receive greater average solar radiation at the top of the canopy (Fig. 1d; Welch Two Sample t -test, $t_{9.93} = -1.89$, $P = 0.089$); coastal sites are significantly warmer (Fig. 1d; Welch Two Sample t -test, $t_{5.01} = -2.86$, $P = 0.035$); and coastal sites receive less precipitation (Fig. 1d; Welch Two Sample t -test, $t_{6.15} = 2.21$, $P = 0.068$).

Amphistomy advantage is greater in coastal leaves —

Amphistomy increases photosynthesis in leaves of coastal 'ilima plants more than that of montane plants. AA was significantly greater than 0 (95% confidence intervals did not overlap 0) in 5 of 6 coastal leaves, but only 1 of 6 montane leaves (Fig. 2; see Fig. S2 for individual curves). Overall, the average AA among coastal and montane leaves is 0.12 [0.077–0.15] and 0.027 [–0.0044–0.057], respectively; the difference in average AA between habitat types is $AA_{\text{coastal}} - AA_{\text{montane}} = 0.089$ [0.04–0.14]. Posterior predictions closely match observed values of A (Fig. S3), indicating an adequate model fit from which we can interpolate between measurements reliably. It also suggests that slight extrapolation beyond the data should be reliable, but this is less certain. When we remove two leaves where extrapolated slightly beyond fitted $A-g_{\text{sw}}$ curves, we estimate that AA_{coastal} is still positive, 0.081 [0.022–0.14], but the difference between coastal and montane leaves is smaller, 0.053 [–0.011–0.12], and confidence intervals slightly overlap 0. Maximum photosynthetic rate was slightly, but not significantly higher in coastal leaves (Welch Two Sample t -test, $t_{9.65} = 1.6$, $P = 0.14$); total stomatal conductance was similar (Welch Two Sample t -test, $t_{9.71} = -0.09$, $P = 0.93$) in coastal and montane leaves

(Fig. S4). Water-use efficiency (A/g_{sw}) was significantly higher in coastal leaves (Welch Two Sample t -test, $t_{9,99} = 2.54$, $P = 0.03$).

Figure 2: Coastal leaves benefit more from amphistomy than montane leaves. A positive amphistomy advantage (y -axis) means that the photosynthetic rate of an amphistomatous leaf is greater than that of an identical pseudohypostomatous leaf at the same overall g_{sw} . Each point-interval is the median posterior estimate plus 95% confidence interval of amphistomy advantage for that leaf. Each leaf is from a different montane (blue) or coastal (orange) site, arranged by habitat and ascending amphistomy advantage within habitat. The longer horizontal bars are the average amphistomy advantage for montane and coastal leaves. g_{sw} , stomatal conductance to water vapor.

Leaf thickness is associated with amphistomy advantage between but not within habitats —

Coastal ‘ilima leaves are 91 [26–164] μm thicker than their montane counterparts. Although coastal leaves are thicker and have greater AA, there is little relationship between leaf thickness and AA within

324 habitats (Fig. 3A; slope = $-0.11 [-0.27-0.036]$).

325 $g_{\text{smax, ratio}}$ **is not associated with amphistomy advantage** —

326 Coastal and montane leaves have similar average $g_{\text{smax, ratio}}$, the ratio of adaxial (upper) to total
327 g_{smax} , the anatomical maximum stomatal conductance to water vapor (Fig. S5); coastal leaves have
328 $0.059 [-0.14-0.28]$ higher $g_{\text{smax, ratio}}$ than montane leaves, but the 95% confidence intervals overlap 0
329 difference. The $g_{\text{smax, ratio}}$ is somewhat bimodal among sites. Some sites in both habitats have leaves
330 with $g_{\text{smax, ratio}} < 0.07$ and others with $g_{\text{smax, ratio}} > 0.2$ (Fig. S5). This is particularly noticeable in
331 montane sites where those on the Big Island of Hawai'i all have low $g_{\text{smax, ratio}}$ whereas those on O'ahu
332 have relatively high $g_{\text{smax, ratio}}$. There is no relationship between $g_{\text{smax, ratio}}$ and AA in either habitat
333 (Fig. 3B; slope = $0.14 [-0.06-0.35]$) in our sample.

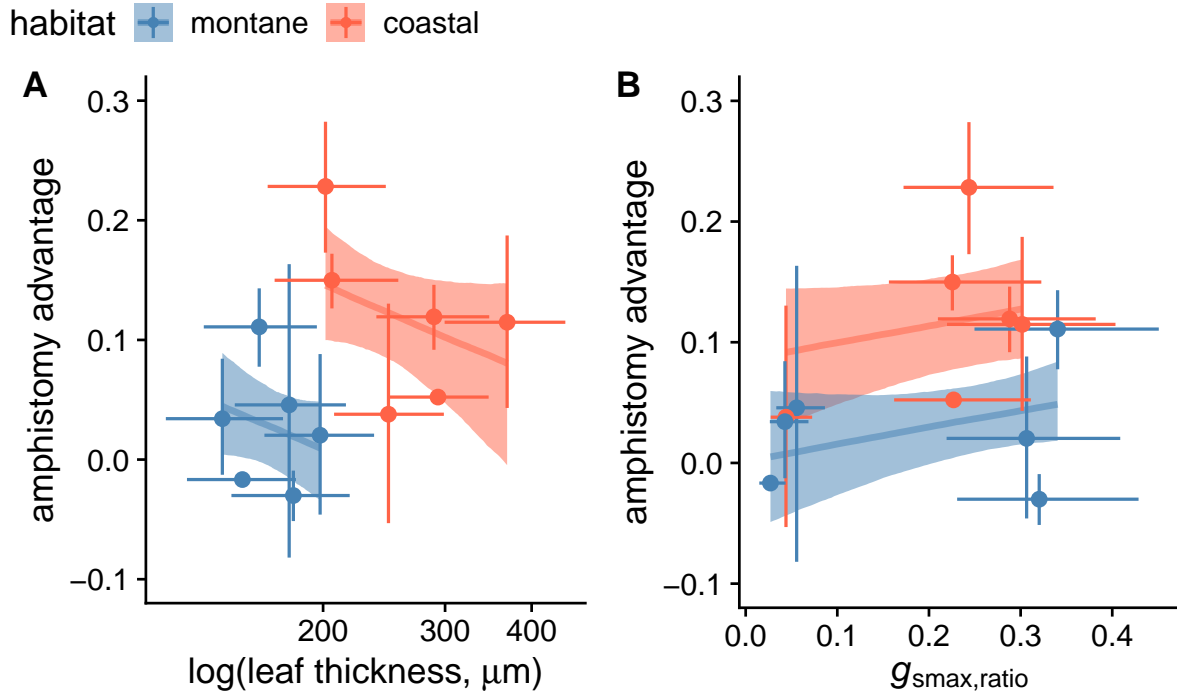

Figure 3: Relationships between leaf amphistomy advantage, (A) leaf thickness and (B) $g_{\text{smax, ratio}}$ among ‘ilima (*Sida fallax*) plants from montane (blue) and coastal (orange) habitats in Hawai‘i. A positive amphistomy advantage (y -axis) means that the photosynthetic rate of an amphistomatous leaf is greater than that of an identical pseudohypostomatous leaf at the same overall g_{sw} . Each point-interval is the median posterior estimate plus 95% confidence interval of the trait value. Each leaf is from a different montane (blue) or coastal (orange) site. Lines are the estimated linear regression of (A) log(leaf thickness) and (B) $g_{\text{smax, ratio}}$ on amphistomy advantage; ribbons are the 95% confident bands of the regression. Symbols: $g_{\text{smax, ratio}}$, anatomical maximum stomatal conductance ratio; g_{sw} , stomatal conductance to water vapor.

DISCUSSION —

Amphistomy is a seemingly simple way that leaves can increase carbon gain without significant additional water loss, yet it is rare in nature and we do not know why. The strong association between amphistomy and sunny, open habitats suggests that amphistomy may benefit sun leaves more than shade leaves, but progress has been limited by the lack of evidence that amphistomy *per se* affects

improves photosynthesis in a given leaf. By experimentally blocking gas exchange through the upper surface in a controlled environment, we directly compared an amphistomatous leaf to an otherwise identical pseudohypostomatous leaf. This allows us to quantify the amphistomy advantage (AA) holding all else constant. Taking advantage of the steep climatic gradients in the Hawaiian archipelago, we applied this new method to show for the first time that sun leaves benefit 4 times more from amphistomy than shade leaves on ‘ilima (*Sida fallax*) plants ($AA_{\text{coastal}} = 0.12$ vs. $AA_{\text{montane}} = 0.027$). Coastal and montane ‘ilima leaves are likely good representatives of classic sun and shade leaf syndromes because 1) they vary in traits like reflective pubescence (Ehleringer and Björkman, 1978) and leaf thickness (Terashima et al., 2001) that typically characterize sun-shade adaptation; and 2) since ‘ilima shrubs are typically $< 1\text{m}$ tall, they are shaded by trees in montane, but not coastal habitats (Fig. 1d). While this result has not yet been validated in other species, our results indicate that part of the reason amphistomatous leaves are found most commonly in high light habitats is that the adaptive benefit is greater in this environment.

If AA is typically greater in sun leaves than shade leaves, it could partially explain the distribution of amphi- and hypostomatous leaves, but the precise mechanism(s) require further study. One hypothesis is that the internal airspace conductance, g_{ias} , from stomata to mesophyll cell walls is lower in thicker sun leaves (Parkhurst, 1978). All else being equal, a leaf with lower g_{ias} will benefit more from amphistomy. Our results partially support this hypothesis. Coastal ‘ilima leaves with high AA (Fig. 2) are thicker than montane leaves, but the relationship between AA and leaf thickness within habitats is actually slightly negative (Fig. 3a), opposite our prediction. Since coastal and montane leaves differ in many respects besides thickness, we do not have enough data to conclude that leaf thickness explains the variation in AA between habitats. Alternatively, other biochemical or anatomical differences between coastal and montane leaves may explain why AA is greater in coastal leaves. The negative relationship, (albeit nonsignificant in that 95% confidence intervals encompassed 0), between leaf thickness and AA could be explained if thicker leaves compensated by having a more porous mesophyll and/or less tortuous airspaces (Théroux-Rancourt et al., 2021).

365 A second natural hypothesis is that amphistomatous leaves with few adaxial (upper) stomata benefit
366 less than those with similar densities on both surfaces. We predicted that leaves with $g_{\text{smax, ratio}}$ closer to
367 0.5 would have higher AA based on biophysical models (Gutschick, 1984a). The logic is that a small
368 number of stomata on the upper surface are insufficient to supply the entire upper mesophyll due to
369 limited lateral diffusion (Morison et al., 2005). Our results do not support this hypothesis. Montane
370 leaves from Big Island sites had low $g_{\text{smax, ratio}}$ and low AA whereas low montane leaves on O‘ahu had
371 high $g_{\text{smax, ratio}}$, but similarly low AA (Fig. 3b). Among coastal sites, the site with the lowest $g_{\text{smax, ratio}}$
372 had the lowest AA, but there was little variation in $g_{\text{smax, ratio}}$ among coastal leaves in our sample. We
373 therefore cannot rule out that a larger sample of coastal leaves with greater variance in $g_{\text{smax, ratio}}$ might
374 support this hypothesis.

375 Two major implications from our study are that 1) photosynthesis in hypostomatous leaves is likely
376 limited by CO₂ concentration drawdown within leaf airspaces; and 2) amphistomy *per se* contributes
377 to, but is not wholly responsible for, higher photosynthetic rates among amphistomatous leaves. The
378 amphistomy advantage we observe in ‘ilima leaves implies decreased CO₂ supply in pseudohypostom-
379 atous leaves because of concentration drawdowns in the leaf airspace. Limited diffusion through the
380 airspace has long been hypothesized to depress photosynthesis in hypostomatous leaves (Parkhurst,
381 1994), with empirical support from helox studies (Parkhurst and Mott, 1990). However, these studies
382 relied on interspecific comparisons of amphi- and hypostomatous leaves that differ systematically in
383 many traits that affect gas exchange and photosynthesis (Xiong and Flexas, 2020). Our experimental
384 approach overcomes this limitation and implies that the drop in CO₂ concentration from substomatal
385 cavities to the upper surface depresses photosynthesis.

386 Among land plants grown in a common garden, amphistomatous leaves have on average nearly 2×
387 higher area-based photosynthetic rates (Xiong and Flexas, 2020), naively implying an AA $\approx \log 2 =$
388 0.69. This is much higher than our estimate of 0.12 among coastal ‘ilima leaves. The most likely expla-
389 nation is that amphistomy is not the only cause of high photosynthetic rate. Indeed, species adapted to

open, high light habitats with amphistomatous leaves also have higher concentrations of Rubisco, overall stomatal conductance, and photosynthetic capacity (Smith et al., 1997; Xiong and Flexas, 2020). For a leaf with high photosynthetic capacity that is well illuminated and hydrated, the major limitation becomes CO₂. Under these conditions, amphistomy may substantially increase photosynthesis, as we observe in coastal 'ilima leaves. Selection on increased photosynthesis under similar conditions may explain why crops leaves tend to increase stomatal density ratio during domestication (Milla et al., 2013).

Three limitations of this study are the small sample size, experimental design that precludes distinguishing genetic from environmental differences in leaf traits, and potentially confounding effects of other environmental differences besides light environment. Understanding the mechanistic basis of higher AA in sun leaves would require much larger sample sizes. Sun leaves tend to be thicker, more densely packed with mesophyll cells, and have greater photosynthetic capacity and higher stomatal conductance, among other traits (Lambers et al., 2008). Each of these factors and others potentially modulate AA. Quantifying the contribution of all these factors requires larger samples and additional measurements that are beyond the scope of this study, but exciting avenues for future research on leaf structure-function relations. Although many morphological traits that distinguish coastal and montane 'ilima populations persist in a common environment (Yorkston and Daehler, 2006), we cannot distinguish between genetic effects and plastic responses to habitat as causes of difference in AA because we measured naturally occurring plants *in situ*. While disentangling genetic and plastic contributions is not necessarily important for understanding the distribution of amphistomatous leaves, it would be insightful to know about genetic and environmental contributions to trait variation. A reciprocal transplant would be able to determine the genetic and environmental contributions, as well their interaction, to trait variance in nature. However, reciprocal transplants cannot control for other differences between coastal and montane habitats besides vegetation height, such as temperature and precipitation. Experimental studies in controlled environments will be necessary to isolate the effect light quantity and quality on AA.

CONCLUSIONS —

This study reports the first direct experimental evidence that having stomata open on both leaf surfaces, amphistomy, increases photosynthesis for a given total stomatal conductance, particularly in leaves from the type of open, sunny habitats where this trait is most common. By developing a straightforward experimental method to block gas exchange through the upper surface, we directly compared the photosynthetic rate of a leaf with gas exchange through both surfaces or just one, holding all other factors constant. In doing so, we found that coastal leaves of the indigenous Hawaiian ‘ilima (*Sida fallax*) enjoyed a greater photosynthetic benefit from amphistomy than nearby montane leaves living in more closed forest. This is not because amphistomatous leaves necessarily have greater leaf surface available for stomata, although that likely influences realized photosynthetic rates in natural populations. Rather, our experiments show that coastal amphistomatous leaves with the same total leaf stomatal conductance photosynthesize more than identical hypostomatous leaves. We cannot yet ascribe the difference in amphistomy advantage between coastal and montane leaves to particular physiological or anatomical variation, but this is a promising area for future research.

Acknowledgments —

The authors thank Kasey Barton and two anonymous reviewers for feedback on an earlier version of this manuscript, the University of Hawai‘i honors council for guidance to GT, Tawn Speetjens for access to one montane site, TM Perez for advice on leaf sectioning, startup funds from the University of Hawai‘i, NSF Award 1929167 to CDM, and NSF Award 2307341 to TNB.

435 Author Contributions —

436 GT and CDM contributed equally to all stages of this project; TNB contributed to development of the
437 method and helped edit the manuscript.
